Classification: Loss function

It would be natural to expect the Average Loss to be Accuracy (fraction of correct predictions).

On a per example basis, the corresponding loss $\mathcal{L}^{(i)}$ would be either 1 or 0, depending on correctness.

This is not the case.

Recall the mapping of probability to prediction

$$\hat{\mathbf{y}^{(i)}} = egin{cases} ext{Negative} & ext{if } \hat{p}^{(i)} < 0.5 \ ext{Positive} & ext{if } \hat{p}^{(i)} \geq 0.5 \end{cases}$$

The prediction for example i changes only when probability $\hat{p}^{(i)}$ crosses the threshold. Suppose the class for example i is Positive: $\mathbf{y^{(i)}} = \text{Positive}$.

• Is our model "better" when

$$\hat{p}^{(\mathbf{i})} pprox 1 \qquad ext{than when} \qquad \hat{p}^{(\mathbf{i})} = 0.5 \ \hat{p}^{(\mathbf{i})} = (.5 - \epsilon) \qquad ext{than when} \qquad \hat{p}^{(\mathbf{i})} pprox 0$$

- The per-example Accuracy is the same in both comparisons
- But a model with probability $\hat{p}^{(i)}$ closer to 1 for a Positive example i would seem to better

There is no *degree* or magnitude of inaccuracy

- Two models may have the same Accuracy even though the probabilities of one may be closer to perfect than the other
- In our search for the best Θ , Accuracy won't be a guide

In mathematical terms: we want our Loss function be be continuous and differentiable. Accuracy (and the per-example analog) satisfies neither. We will introduce Binary Cross Entropy loss to overcome this difficulty. Think of Binary Cross Entropy as a continuous analog of Accuracy.

Binary Cross Entropy

Let's encode the Positive labels $\mathbf{y^{(i)}}$ with the number 1 and Negative labels with the number 0. The loss for example i will be defined as $\$ \loss^\ip_\Theta = \begin{cases}

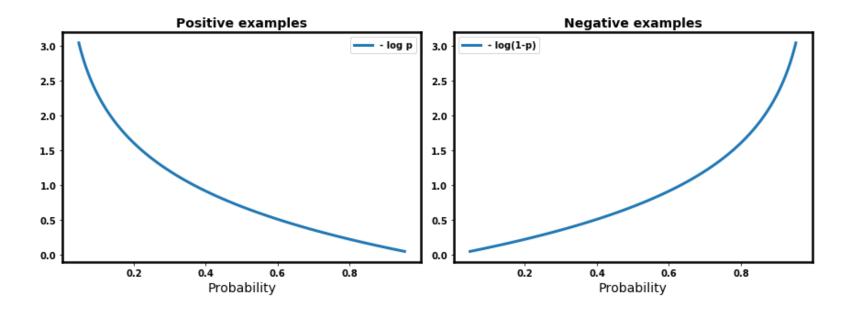

- \log(\hat{p}) & \textrm{if } & \y^\ip = 1 \
- \log(1-\hat{p}) & \textrm{if } & \y^\ip = 0 \ \end{cases} \$\$

Note the negative signs:

• The term being negated is a Utility (which we want to maximize)

A plot will give us some intuition.

In [4]: svmh.plot_log_p(x_axis="Probability")

- For Positive examples: the loss approaches 0 as the predicted probability approaches the correct value (1).
- For Negative examples: the loss approaches () as the predicted probability approaches the correct value (0).

In a Deep Dive (after the introduction of a bit of math) we will gain a greater appreciation it's meaning.

For now: be content that Binary Cross Entropy seems to have the right slope and asymptotic behavior.

Because only one of ${\bf y^{(i)}}$ and $(1-{\bf y^{(i)}})$ is non zero, we can re-write the two-case statement into a single expression

$$\mathcal{L}_{\Theta}^{(\mathbf{i})} = -\left(\mathbf{y^{(i)}} * \log(\hat{p}^{(\mathbf{i})}) + (1 - \mathbf{y^{(i)}}) * \log(1 - \hat{p}^{(\mathbf{i})})\right)$$

This expression is referred to as *Binary Cross Entropy*; it and the multi-class version will become quite familiar going forward.

The Loss for the entire training set is simply the average (across examples) of the Loss for the example

$$\mathcal{L}_{\Theta} = rac{1}{m} \sum_{i=1}^{m} \mathcal{L}_{\Theta}^{(\mathbf{i})}$$

Cost function for Multinomial Classification: Cross Entropy

A Multinomial Classifier (when categories/classes ||C||>2) can be created from multiple Binary Classifiers

- ullet Create a separate Binary Classifier for each $c\in C$
- The classifier for category c attempts to classify
 - Each example with target category of *c* as Positive
 - All other examples as Negative
- ullet Combine the ||C|| classifiers to produce a vector \hat{p} of length ||C||
 - lacksquare normalize across $c \in C$ to sum to 1
 - ullet \hat{p}_c denotes the normalized value for category c
 - Notation abuse: subscripts should be integers, not categories

Both the target ${f y}$ and the prediction $\hat p$ are represented as vectors of length ||C||

- We write \mathbf{y}_c, \hat{p}_c to denote the element of the vector corresponding to category c
- Each vector can be interpreted as a probability distribution, e.g.

$$\forall c \in C : \mathbf{y}_c \geq 0$$

$$\sum_{c \in C} \mathbf{y}_c = 1$$

- y was created with One Hot Encoding (OHE), so properties satisfied by construction
- $\,\blacksquare\,\, \hat{p}_c$ satisfies the properties by virtue of the normalization of the predictions of the ||C|| binary classifiers

With \mathbf{y},\hat{p} encoded as a vectors, per example Binary Cross Entropy can be generalized to $||C|| \geq 2$ categories:

$$\mathcal{L}_{\Theta}^{(\mathbf{i})} = -\sum_{c=1}^{||C||} \left(\mathbf{y}_c^{(\mathbf{i})} * \log(\hat{\mathbf{p}}_c^{(\mathbf{i})})
ight)$$

This is the multinomial analog of Binary Cross Entropy and is called **Cross Entropy**.

Cross Entropy can be interpreted as a measure of the "distance" between distributions ${f y}$ and \hat{p}

- Minimized when they are identical
- We will use Cross Entropy in the future both as a Loss function and a way of comparing probability distributions
